## 1 Introduction to Template Patterns

Template expansion provides a pure untyped lambda calculus. All equality is extensional and the calculus supports higher-order functions (templates) with annotations at invocation, but not declaration, time.<sup>1</sup> This section goes over the encoding of lambda calculus in the template system.

### 1.1 Encoding constants

Constants are simply structs, classes, or other types that don't take template parameters. It isn't a problem if they do take template parameters, of course; those will simply be specified later once the constant has propagated through the lambda expansion.

**Listing 1** examples/introduction/constants.hh

```

1 // Defining a constant term
2 struct foo {
3     enum {value = 10};
4 };
5
6 // Defining a global constant also_foo = foo
7 typedef foo also_foo;
8
9 // Defining two templated terms that act as constants
10 template<class t> struct has_a_field {
11     t field;
12 };
13
14 template<int n> struct has_a_number {
15     enum {number = n};
16 };

```

---

<sup>1</sup>This makes it untyped. C++ templates also support function types using nested template syntax – see [section 1.4](#).

## 1.2 First-order function encoding

The idea is to have structs that represent terms of the calculus. If they are templates, then they represent functions (which are also terms). For example:

**Listing 2** examples/introduction/first-order-functions.cc

```
1 #include <iostream>
2 #include "constants.hh"
3
4 // Defining the identity function, where the result
5 // can be retrieved by specifying bar<T>::type
6 template<class t> struct bar {
7     typedef t type;
8 };
9
10 // Defining a global constant identity_result = bar(also_foo)
11 typedef bar<also_foo>::type identity_result;
12
13 int main () {
14     std::cout << "foo::value          = " <<
15                 foo::value              << std::endl <<
16                 "also_foo::value       = " <<
17                 also_foo::value         << std::endl <<
18                 "identity_result::value = " <<
19                 identity_result::value  << std::endl;
20 }
```

In practice there is some difficulty already. Notice the use of `::type` to retrieve the value of a function application. This slot had to be assumed by the caller; it is similar to JavaScript code like this:

**Listing 3** examples/introduction/unfriendly-identity.js

```
1 // An unfriendly identity function.
2 var identity = function (x) {
3     return {type: x};
4 };
5
6 // Invocations must now look like this:
7 var y = identity(x).type;
```

Having issues like this percolating through the design can be a real problem. Unless the slot is passed to every invocation site,<sup>2</sup> invocations will be divergent and will create errors. This means that return values should be unified to a single slot, in this library (and the Boost MPL) called `::type`.<sup>3</sup>

<sup>2</sup>It also must be forwarded, which isn't possible in C++ to the best of my knowledge.

<sup>3</sup>This may seem counter-intuitive, since the types here encode values in lambda-calculus. However, it does serve a mnemonic purpose later when value types are used as template parameters, and

So we establish some conventions up front. Whenever you define a constant, it is used as-is without a contained `typedef` that we have to know about. This is OK because we shouldn't ever make assumptions about the members of types that are used as template parameters.

### 1.3 Higher-order function encoding

Higher-order functions are possible by encoding slots for invocations.<sup>4</sup> We do this by declaring another template inside the first:

Listing 4 examples/introduction/higher-order-functions.cc

```
1 #include <iostream>
2 #include "constants.hh"
3
4 // Defining the K combinator
5 template<class t>
6 struct k {
7     template<class u>
8     struct apply {
9         typedef t type;
10    };
11 };
12
13 // Using that on two types
14 typedef has_a_number<5> t1;
15 typedef has_a_number<6> t2;
16 typedef k<t1>::apply<t2>::type should_be_t1;
17
18 int main () {
19     std::cout << "t1::number          = " << t1::number          << std::endl <<
20               "should_be_t1::number = " << should_be_t1::number << std::endl;
21 }
```

In this example, `k` has a call slot `apply` that ultimately provides the value. So, for example, `k<x>::apply<y>::type` is equivalent to the more concise `k x y` in Haskell, or `((k x) y)` in Scheme.

At this point it should be clear that nothing is standardized here. Top-level functions are invoked directly, whereas returned functions use `::apply<x>`. Type results from template invocations are accessed as `::type`. One way to go about fixing it is to make a rule that a function gets encoded a bit less directly:

---

dependent value-type relations are established. Once this happens it becomes useful to explicitly distinguish between type template parameters and value template parameters.

<sup>4</sup>This is equivalent to the distinction between pure, extensional object-oriented programming and pure, extensional functional programming. In the latter, term juxtaposition (e.g. `f x`) constitutes invocation of the default slot, generally referred to as *apply*. In the former, slots are explicitly named, as would be the case in a language such as Java – thus juxtaposition has no meaning on its own.

**Listing 5** examples/introduction/indirect-functions-broken.cc

```
1 // Encoding the K combinator uniformly, but with compile errors
2 struct k {
3     template<class t>
4     struct apply {
5         template<class u>
6         struct apply {
7             typedef t type;
8         };
9     };
10 };
```

However, if you compile it you get an error stating that you can't define a nested struct with the same name as the outer one. The solution is to use an intermediate `::type` dereference to wrap the inner `::apply<x>`.

**Listing 6** examples/introduction/indirect-functions.cc

```
1 #include <iostream>
2 #include "constants.hh"
3
4 // Encoding the K combinator uniformly
5 struct k {
6     template<class t>
7     struct apply {
8         struct type {
9             template<class u>
10            struct apply {
11                typedef t type;
12            };
13        };
14    };
15 };
16
17 typedef has_a_number<5> t1;
18 typedef has_a_number<6> t2;
19 typedef k::apply<t1>::type::apply<t2>::type should_be_t1;
20
21 int main () {
22     std::cout << "t1::number          = " << t1::number          << std::endl <<
23         "should_be_t1::number = " << should_be_t1::number << std::endl;
24 }
```

At this point a nice pattern emerges. Whenever we apply a function to something, we get its `::type` as well. So constants map to themselves, and function invocations are all of the form `f::apply<...>::type`.

## 1.4 Higher-order function type signatures

C++ lets you specify type signatures for higher-order templates. This can be useful to ensure that a function possesses at least a certain Church arity<sup>5</sup> or takes at least so many arguments. It also provides some notational convenience at invocation-time.

Here is the Haskell function that we will model in C++ templates:

**Listing 7** examples/introduction/apply-two-function.hs

```
1 apply_two :: ((a, a) -> b) -> a -> b
2 apply_two f x = f (x, x)
```

In template metaprogramming it isn't possible to express the constraints about values, but we can express constraints about arity and function status:

**Listing 8** examples/introduction/apply-two-function.cc

```
1 #include <iostream>
2 #include "constants.hh"
3
4 // Encoding the type signature as a template parameter specification
5 struct apply_two {
6     template<template<class arg1, class arg2> class f>
7     struct apply {
8         struct type {
9             template<class x>
10             struct apply {
11                 typedef f<x, x> type;
12             };
13         };
14     };
15 };
16
17 // An example value for f
18 template<class x, class y>
19 struct sample_f {
20     typedef x x_type;
21     typedef y y_type;
22 };
23
24 typedef has_a_number<10> t1;
25 typedef has_a_number<12> t2;
26 typedef apply_two::apply<sample_f>::type::apply<t1>::type two_of_t1;
27
28 int main () {
```

---

<sup>5</sup>I use this term to refer to the arity of the uncurried form of the function. For example, the Church arity of  $\lambda x.\lambda y.x$  is 2, since uncurrying yields  $\lambda(x,y).x$ .

```

29     std::cout << "t1::number          = " << t1::number << std::endl <<
30         "two_of_t1::x_type::number = " << two_of_t1::x_type::number << std::endl <<
31         "two_of_t1::y_type::number = " << two_of_t1::y_type::number << std::endl;
32 }

```

The parameter definition `<template<class arg1, class arg2> class f>` is equivalent to the Haskell type signature `f :: (a, b) -> c`; none of the individual types are specified, but the template must be invoked on two parameters or not invoked at all.<sup>6</sup> The other thing of note is that you can arbitrarily refine the left-hand side; for example:

```

template<template<template<class x> class f,
                template<class y> class g> class compose>
struct composer {...};

```

This is equivalent to `composer :: ((a -> b), (c -> d)) -> e`. As far as I know there is no way to specify anything about the return type of a function using template syntax.

I'm not using template types in this project for a couple of reasons. First, declaring formals uses names (I'm actually not sure whether those names are considered reserved by C++, but I assume so). Second, it isn't possible to encode slot types, and all invocation in the lambda-calculus encoding is done with the `::apply` slot.

## 1.5 Conditionals

Templates don't model conditionals *per se*. Rather, you can create conditionals by using pattern matching and explicit specialization. There are some weird limitations about this, but here is the basic idea:

**Listing 9** examples/introduction/specialization.cc

```

1  #include <iostream>
2  #include "constants.hh"
3
4  // General case
5  template<class t>
6  struct piecewise {
7      typedef t type;
8  };
9
10 // When t = has_a_number<50>, do this instead
11 template<>
12 struct piecewise<has_a_number<50>> {
13     typedef has_a_number<100> type;

```

<sup>6</sup>Note that at this point I'm not referring to invocation using the `::apply` convention established earlier. This invocation is just regular template expansion.

```

14 };
15
16 typedef piecewise<has_a_number<3>>::type general;
17 typedef piecewise<has_a_number<50>>::type specialized;
18
19 int main () {
20     std::cout << "general::number    = " << general::number    << std::endl <<
21                 "specialized::number = " << specialized::number << std::endl;
22 }

```

### 1.5.1 Limitations of inner specialization

Because terminal (i.e. non-expanding) types are extensionally equivalent, pattern matching can be used to reliably specialize template expansions. The only case where this doesn't work is inside a class:

**Listing 10** examples/introduction/inner-specialization-broken.cc

```

1 template<class t>
2 struct container {
3     template<class u>
4     struct piecewise {
5         typedef u type;
6     };
7
8     // Compiler complains about this:
9     template<>
10    struct piecewise<int> {
11        typedef t type;
12    };
13 };
14
15 typedef container<int>::piecewise<int>::type foo;

```

The solution to this problem is to break the inner class outside of the outer one and uncurry its arguments:

**Listing 11** examples/introduction/inner-specialization.cc

```

1 #include <iostream>
2 #include "constants.hh"
3
4 namespace inside_container {
5     template<class t, class u>
6     struct piecewise {
7         typedef u type;
8     };
9

```

```

10     template<class t>
11     struct piecewise<t, int> {
12         typedef t type;
13     };
14 }
15
16 template<class t>
17 struct container {
18     template<class u>
19     struct piecewise {
20         typedef typename inside_container::piecewise<t, u::type> type;
21     };
22 };
23
24 typedef has_a_number<1> t1;
25 typedef has_a_number<2> t2;
26 typedef container<t1>::piecewise<t2>::type general;
27 typedef container<t1>::piecewise<int>::type specialized;
28
29 int main () {
30     std::cout << "general::number    = " << general::number    << std::endl <<
31               "specialized::number = " << specialized::number << std::endl;
32 }

```

The namespace here isn't necessary, but it hides what normally gets hidden when you create an anonymous closure. Also notice that it must be declared before `container` due to C++'s forward-reference semantics.<sup>7</sup>

## 2 Metaprogramming in Value Space

Without using any particular encoding, this section provides a few examples of template metaprogramming in action. Each example has been factored down by preprocessor macros to show the structure of the code. Also, these examples are not necessarily representative of best practices, nor do they scale well.

### 2.1 Fibonacci numbers (explicit specialization)

This is some metaprogramming in value-space. Constants are evaluated and folded at compile-time, so the expression term below can be used to perform arithmetic evaluation. This example defines one general form of `fibonacci`, and two specific forms for an inductive process with two base cases. It also shows the lack of generality of piecewise definitions; while it is possible to specify a template for given values, implementing the classic compact definition of the function:

---

<sup>7</sup>Despite this, template expansion is generally lazy in other ways.

$$f(n) = \begin{cases} f(n-1) + f(n-2) & n \geq 2 \\ n & n < 2 \end{cases}$$

is not possible through specialization without enumerating every value of  $n$  below or above 2. In this section we implement a more straightforward definition:

$$f(n) = \begin{cases} 0 & n = 0 \\ 1 & n = 1 \\ f(n-1) + f(n-2) & \text{otherwise} \end{cases}$$

The compact definition is possible, however. The key is to encode that condition separately and specialize on a boolean parameter. That is implemented in [section 2.2](#).

**Listing 12** examples/introduction/fibonacci.cc

```

1 #include <iostream>
2
3 #define letrec(name, params, defaults, expression) \
4   template params \
5   struct name defaults { \
6     enum { value = expression }; \
7   };
8
9 #define call(name, params...) (name<params>::value)
10
11 letrec(fibonacci, <int n>, , call(fibonacci, n - 1) + call(fibonacci, n - 2))
12 letrec(fibonacci, <>, <0>, 0)
13 letrec(fibonacci, <>, <1>, 1)
14
15 int main () {
16   std::cout << "fibonacci<10>::value = " << fibonacci<10>::value << std::endl;
17 }
```

## 2.2 Fibonacci numbers (piecewise definition)

As mentioned in [section 2.1](#), it is possible to encode the Fibonacci function using a general conditional instead of explicitly specializing the two base values of 0 and 1. This example doesn't motivate its full utility (better would be a densely piecewise function such as the absolute value), but you can easily extrapolate from the design pattern.

The first step is to isolate the cases. For the piecewise Fibonacci function:

$$f(n) = \begin{cases} n & n < 2 \\ f(n-1) + f(n-2) & n \geq 2 \end{cases}$$

A boolean contains enough information to encode which branch should be taken. I'll use  $n < 2$  as the predicate, so a value of `true` should result in  $n$  while a value of `false` should result in  $f(n-1) + f(n-2)$ .

Here is the obvious way to go about it, though it doesn't work because of mutual dependencies in the definitions:

**Listing 13** examples/introduction/fibonacci-piecewise-broken.cc

```

1  template <bool n_lt_2, int n>
2  struct fibonacci_case {
3      enum { value = fibonacci<n - 1>::value + fibonacci<n - 2>::value };
4  };
5
6  template <int n>
7  struct fibonacci_case <true, n> {
8      enum { value = n };
9  };
10
11 template <int n>
12 struct fibonacci {
13     enum { value = fibonacci_case<(n < 2), n>::value };
14 };

```

C++ needs to know about template types before you hit them. Because there isn't a way to forward-define templates, we have to get a little bit more creative:

**Listing 14** examples/introduction/fibonacci-piecewise.cc

```

1  #include <iostream>
2
3  template <class f, bool n_lt_2, int n>
4  struct fibonacci_case {
5      enum { value = f::template recursive<n - 1>::value +
6                  f::template recursive<n - 2>::value };
7  };
8
9  template <class f, int n>
10 struct fibonacci_case <f, true, n> {
11     enum { value = n };
12 };
13
14 struct fibonacci_piecewise {
15     template <int n>
16     struct recursive {
17         enum { value = fibonacci_case<fibonacci_piecewise, (n < 2), n>::value };
18     };
19 };

```

```

20
21 template <int n>
22 struct fibonacci {
23     enum { value = fibonacci_pieewise::template recursive<n>::value };
24 };
25
26 int main () {
27     std::cout << "fibonacci<10>::value = " << fibonacci<10>::value << std::endl;
28 }

```

Note the wrapping of `fibonacci_pieewise::recursive`. This is necessary because within the scope of a template, the name of the templated construct refers to the specialized form, not the template itself. For example:

**Listing 15** examples/introduction/self-reference-broken.cc

```

1 template <int n>
2 struct foo {
3     typedef foo bar;
4 };
5
6 typedef foo<10>::bar should_be_a_template;
7 typedef should_be_a_template<10> problem;

```

In this example, `should_be_a_template` isn't a template at all; it's the expanded form of `foo`, which has already been specialized to `foo<10>`. The compiler complains when `typedefing problem` because we are trying to expand something that isn't a template.

The solution is to wrap the template inside a non-template outer struct, as the working Fibonacci example demonstrates. This enables you to refer unambiguously to the outer struct and then explicitly dereference the inner template, which will not be specialized at that point.

## 2.3 Linked list

This is a simple model of a data structure in value-space. For scalability it would be better to use types for the head and tail, but for simplicity the example is restricted to using values.

The `q` function in this example works around a limitation of the preprocessor. [Section 3.1](#) covers this in more detail.

**Listing 16** examples/introduction/linked-list.cc

```

1 #include <iostream>
2
3 #define function(name, params, values...) \
4     template <params> \
5     struct name { \
6         enum { values }; \

```

```

7     }
8
9     // Prevents commas from separating the arguments:
10    #define q(args...) args
11
12    function(cons, q(class X, class Y), car = X::value, cdr = Y::value);
13    function(car, class T, value = T::car);
14    function(cdr, class T, value = T::cdr);
15    function(int_wrapper, int n, value = n);
16
17    int main () {
18        std::cout << "car(cons(5, 6)) = " <<
19                car<cons<int_wrapper<5>, int_wrapper<6>>>::value << std::endl;
20    }

```

## 2.4 Church-encoded lists, map, and filter

This is a more involved example that uses curried templates and a Church encoding. Note the transition between value-space and type-space achieved by using `select`. `select` effectively serves as a map from `bool` to either `head` or `tail`.

Listing 17 examples/introduction/church-lists.cc

```

1  #include <iostream>
2
3  #define fn(args...)      template <args> struct
4  #define lambda(args...) template <args> struct apply
5
6  #define lift(name, xs...) template <xs> class name
7  #define call(v, xs...)   typename v::template apply<xs>::type
8
9  #define let(var, value...) private: typedef value var
10 #define ret(value...)      public: typedef value type
11 #define val(e)              public: struct type { enum { value = e }; }
12
13 struct head {lambda(class h, class t) {ret(h);}};
14 struct tail {lambda(class h, class t) {ret(t);}};
15
16 namespace _select {
17     lambda(bool b) {ret(head);};
18     lambda() <false> {ret(tail);};
19 }
20
21 struct select {
22     lambda(class t) {ret(call(_select, t::type::value));};

```

```

23 };
24
25 fn(class h, class t) cons {
26     lambda(class f) {
27         ret(call(f, h, t));
28     };
29 };
30
31 struct nil {
32     typedef int type;
33 };
34
35 struct map {
36     lambda(class f, class cell) {
37         let(mapped_head, call(f, call(cell, head)));
38         let(mapped_tail, call(map, f, call(cell, tail)));
39         ret(cons<mapped_head, mapped_tail>);
40     };
41
42     lambda(class f) <f, nil> {
43         ret(nil);
44     };
45 };
46
47 struct filter {
48     lambda(class f, class cell) {
49         let(h, call(cell, head));
50         let(filtered_tail, call(filter, f, call(cell, tail)));
51         let(choices, cons<cons<h, filtered_tail>, filtered_tail>);
52         let(selector, call(select, call(f, h)));
53
54         ret(call(choices, selector));
55     };
56
57     lambda(class f) <f, nil> {
58         ret(nil);
59     };
60 };
61
62 fn(int n) int_wrap {
63     val(n);
64 };
65
66 fn(class x) plus {
67     lambda(class y) {
68         val(x::type::value + y::type::value);

```

```

69     };
70 };
71
72 fn(int n) is_divisible_by {
73     lambda(class x) {
74         val(x::type::value % n == 0);
75     };
76 };
77
78 int main () {
79     typedef cons<int_wrap<5>, cons<int_wrap<6>, nil>> the_list;
80     typedef plus<int_wrap<6>> the_function;
81     typedef is_divisible_by<3> the_criterion;
82     typedef filter::apply<the_criterion, the_list>::type the_short_list;
83     typedef map::apply<the_function, the_short_list>::type the_result;
84     typedef the_result::apply<head> should_be_seven;
85
86     std::cout << "head(map(x -> x + 6, filter(x % 3 == 0, list(5, 6)))) = " <<
87         should_be_seven::type::value << std::endl;
88 }

```

The use of cons to represent the possible outcomes of a decisional isn't a new idea. It's key to the use of `select`, which will return either `head` or `tail`. We then apply the cons cell to that outcome to obtain the conditional result. The only problem with this approach is that both possibilities end up getting evaluated regardless of the condition. So in general, church-encodings of booleans and other conditionals has the caveat that it may cause infinite recursion. Most conditionals should probably be implemented using specialization (see [section 2.2](#)) to avoid this problem.

### 3 Preprocessor Definitions

The goal of this section is to implement a layer of abstraction over the base template constructs. Roughly, the operations are:

1. Defining a global constant
2. Defining a local variable
3. Applying a function to an expression
4. Returning a value from a function
5. Defining a named function

Each of these operations has a standard form.<sup>8</sup> The definition of a shorthand for each is given in the following subsections.

### 3.1 Preprocessor limitations

One notable limitation of the C preprocessor when working with templates is that it doesn't treat < and > as nested parentheticals.<sup>9</sup> This has the unfortunate effect of splitting on commas that separate template parameters, e.g.:

```
#define f(x) ...

template<class x, class y>
struct foo {...};

f(foo<bar, bif>);    // Error here; too many arguments
```

In value-space you can deal with this by explicitly parenthesizing expressions, but parentheses aren't a transparent construct in type-space. The way I'm getting around this for now is to make macros variadic and always put any template invocations at the end:

```
#define f(x...) typedef x bar;
```

This will preserve the commas in the original expression, although its use may be limited to the GNU preprocessor.<sup>10</sup> This macro is called `q` and is defined in [section 3.2](#).

Another limitation has to do with brace matching. In order to write syntax in a natural way, it is helpful to write macros that behave more or less with standard C syntax; that is, the block occurs after the macro invocation:

```
macro_invocation(x, y, z) { block }
```

However, a problem arises when the macro is responsible for expanding two sets of braces, as might be the case for a nested `struct`:

```
// Need to generate this code:
struct foo {
    struct bar { stuff };
};
```

---

<sup>8</sup>There are two for [item 3](#); one form is used outside of a function body and the other is used inside. The difference has to do with disambiguating template expansions and is covered in [section 3.5](#). Also a great article about the role of `typename` in C++, its uses, and its limitations: <http://pages.cs.wisc.edu/~driscoll/typename.html>.

<sup>9</sup>It wouldn't be possible for it to do the right thing here anyway, since the preprocessor sees code before types have been defined. However, template punctuation was an unfortunate choice considering its ambiguity with relational operators, and the fact that relational operators are always ungrouped while template parameter delimiters are always grouped.

<sup>10</sup>A more standard way to do this is to use the `__VA_ARGS__` builtin and an anonymous ellipsis.

```

// This macro definition won't do it:
#define generate() \
    struct foo { \
        struct bar

// This code:
generate() {
    stuff
};

// Expands to this:
struct foo {
    struct bar {
        stuff
    };
    // <- No closing brace!

```

However, certain cases where this would have been used can be worked around. It comes into play when defining templates as functions; see [section 3.8](#).

## 3.2 Variadic protection

As mentioned earlier, we need a way to work around the C preprocessor's inability to identify `<>` groups for template parameters. The simplest way is to introduce a protecting macro `q` to quote a variadic construct but group it into just one argument.

Listing 18 `preprocessor/q.hh`

```

1 #ifndef LISP_PREPROCESSOR_DEFINE
2 # define LISP_PREPROCESSOR_Q_ENABLED
3 # define q(x...) x
4 #else
5 # undef LISP_PREPROCESSOR_Q_ENABLED
6 # undef q
7 #endif

```

## 3.3 Global constants

A global constant is just a standalone struct. To encode this, we create the `def()` macro, which basically just expands out to `struct`. However, it is a bit clearer than its expansion, especially in the context of defining functions and values.

This module, like all of the preprocessor utilities, can be enabled and disabled multiple times during preprocessing. This prevents the macros from

interfering with regular code, which ultimately enables clearer macro naming. The mechanism that governs enabling and disabling is the `LISP_PREPROCESSOR_DEFINE` preprocessor variable. If defined, then the header is run in “definition mode” and will create macros. Otherwise it will undefine the macros. You can see whether a macro is defined as well; each header file defines a macro called `LISP_PREPROCESSOR_X_ENABLED`, where `X` is the upper-case name of the header file. This macro is undefined when the header is disabled.

Note that you shouldn’t ever include this header file directly. See [section 3.10](#) for a simple interface to enable and disable preprocessor macros.

**Listing 19** `preprocessor/def.hh`

```
1 #ifndef LISP_PREPROCESSOR_DEFINE
2 # define LISP_PREPROCESSOR_DEF_ENABLED
3 # define def(name) struct name
4 #else
5 # undef LISP_PREPROCESSOR_DEF_ENABLED
6 # undef def
7 #endif
```

### 3.4 Local variables

Within a struct, local variables are prefixed with `private`.

**Listing 20** `preprocessor/let.hh`

```
1 #ifndef LISP_PREPROCESSOR_DEFINE
2 # define LISP_PREPROCESSOR_LET_ENABLED
3 # define let(name, value...) private: typedef value name
4 # define local_def(name) private: struct name
5 #else
6 # undef LISP_PREPROCESSOR_LET_ENABLED
7 # undef let
8 # undef local_def
9 #endif
```

### 3.5 Function application

It is assumed that function application involves dependent types.<sup>11</sup> In that case, the default `call(x, ...)` works fine. If, however, the function call’s types are already resolved and do not depend on template variables, then you will probably want to use `call_static` instead.

**Listing 21** `preprocessor/call.hh`

```
1 #ifndef LISP_PREPROCESSOR_DEFINE
```

<sup>11</sup>In the C++ sense, not the type-theoretic sense. C++ dependent types are the transitive closure of template variables through the expansion graph.

```

2 # define LISP_PREPROCESSOR_CALL_ENABLED
3 # define call(lhs, rhs...) typename lhs::template apply<rhs>::type
4 # define call_static(lhs, rhs...) lhs::apply<rhs>::type
5 #else
6 # undef LISP_PREPROCESSOR_CALL_ENABLED
7 # undef call
8 # undef call_static
9 #endif

```

### 3.6 Returning a value

It is straightforward to return a named value. This always takes the form `typedef x type`, where `x` is the value to be returned. For simplicity's sake, I'm going to assume that whatever value should be returned has a name to preserve the uniformity of the return expansion. Note that it is prefixed with `public` to override any previous local variables that were defined.

Listing 22 `preprocessor/ret.hh`

```

1 #ifndef LISP_PREPROCESSOR_DEFINE
2 # define LISP_PREPROCESSOR_RET_ENABLED
3 # define ret(value...) public: typedef value type
4 #else
5 # undef LISP_PREPROCESSOR_RET_ENABLED
6 # undef ret
7 #endif

```

### 3.7 Defining a named function

To remain in the mindset of the model C++ uses for template specialization, defining a named function is a two-step process. First, you define the outer struct using `def()` (see [section 3.3](#)). Inside that you can specify the cases using the `when()` macro.

Listing 23 `preprocessor/when.hh`

```

1 #ifndef LISP_PREPROCESSOR_DEFINE
2 # define LISP_PREPROCESSOR_WHEN_ENABLED
3 # define when(parameters...) template <parameters> struct apply
4 #else
5 # undef LISP_PREPROCESSOR_WHEN_ENABLED
6 # undef when
7 #endif

```

### 3.8 Defining and returning closures

It is fairly simple to return a closure. The idea is that you create a local named function and then return that by name, so to implement the K combinator, for example, you would do something like this:

```
def(k) {  
  when(class x) {  
    local_def(inner) {  
      when(class y) {  
        ret(x);  
      };  
    };  
  
    ret(inner);  
  };  
};
```

However, that's a bulky representation given that no explicit specialization is occurring. It would be tempting to implement a defun macro like this:

```
#define defun(name, params...) \  
  def(name) {}; \  
  template<params> struct name::apply
```

however C++ doesn't allow you to define inner structs after the fact.<sup>12</sup> What is possible, on the other hand, is to use a shorthand macro to return a single expression. As long as you're not using any let variables, this is a quick and easy way to do it. Unfortunately it is necessary to use the q macro here, since otherwise it would be impossible to distinguish the parameters from the return value.

Listing 24 preprocessor/fn.hh

```
1 #ifndef LISP_PREPROCESSOR_DEFINE  
2 # define LISP_PREPROCESSOR_FN_ENABLED  
3 # define fn(params, return_value...) {\  
4     public: template<params> struct apply { \  
5         ret(return_value); \  
6     }; \  
7 }  
8 #else  
9 # undef LISP_PREPROCESSOR_FN_ENABLED  
10 # undef fn  
11 #endif
```

The usage of this construct, then, would be something like this:

---

<sup>12</sup>While it might allow a forward definition for a normal struct, this isn't possible for a templated struct, so we're back to square one.

```

def(k) {
  when(class x) {
    local_def(inner) fn(class y, x);
    ret(inner);
  }
};

```

### 3.9 Defining values

You can annotate a type with a value. This is necessary when projecting integer computations into type-space (e.g. when using `cons::from_bool`, defined in [section ??](#)). The simplest way to do it is to use `let_value`, defined here:

Listing 25 `preprocessor/value.hh`

```

1 #ifndef LISP_PREPROCESSOR_DEFINE
2 # define LISP_PREPROCESSOR_VALUE_ENABLED
3 # define let_value(name, v...) \
4     private: struct name { enum { value = v }; };
5 #else
6 # undef LISP_PREPROCESSOR_VALUE_ENABLED
7 # undef let_value
8 #endif

```

The use case for this macro is covered more extensively in [section 1.5](#).

### 3.10 Preprocessor interface

Rather than using the files above, it's better to include these header files to enable or disable the preprocessor macros.

Listing 26 `preprocessor/begin.hh`

```

1 #ifndef LISP_PREPROCESSOR_DEFINE
2 #define LISP_PREPROCESSOR_DEFINE
3 #include "preprocessor/all.hh"
4 #endif

```

Listing 27 `preprocessor/end.hh`

```

1 #ifdef LISP_PREPROCESSOR_DEFINE
2 #undef LISP_PREPROCESSOR_DEFINE
3 #include "preprocessor/all.hh"
4 #endif

```

This file is used internally to include all of the modules listed in the previous subsections:

Listing 28 `preprocessor/all.hh`

```

1 #include "preprocessor/q.hh"
2 #include "preprocessor/def.hh"
3 #include "preprocessor/let.hh"
4 #include "preprocessor/call.hh"
5 #include "preprocessor/ret.hh"
6 #include "preprocessor/when.hh"
7 #include "preprocessor/fn.hh"
8 #include "preprocessor/value.hh"

```

### 3.11 Core interface

These headers contain things to abstract away the process of defining modules. Usage is like this:

```

#include "module/begin.h"
// module code
#include "module/end.h"

```

**Listing 29** module/begin.hh

```

1 #include "preprocessor/begin.hh"
2 namespace lisp {

```

**Listing 30** module/end.hh

```

1 }
2 #include "preprocessor/end.hh"

```

## 4 List Functions

This section implements a Church-encoded linked list that forms the basic data structure for the  $\beta$  rewrite process implemented in [section 5](#).

### 4.1 Cons cells

The  $\beta$  rewrite system assumes the existence of two data types. One is the *term*, which corresponds to a value that might get replaced, and the other is a cons cell of two values. The first step to modeling these things is defining a cons cell, which for this system is Church-encoded:

**Listing 31** core/cons.hh

```

1 #ifndef CORE_CONS_HH
2 #define CORE_CONS_HH
3
4 #include "module/begin.hh"

```

```

5 def(cons) {
6   when(class h, class t) {
7     local_def(closure) fn(class f, call(f, h, t));
8     ret(closure);
9   };
10
11   def(hd) fn(q(class h, class t), h);
12   def(tl) fn(q(class h, class t), t);
13
14   def(nil) fn(class f, nil);
15 };
16
17 #include "module/end.hh"
18
19 #endif

```

**Listing 32** tests/core/cons.cc

```

1 #include "core/cons.hh"
2 #include "unit/test.hh"
3 #include "unit/fixtures.hh"
4
5 deftest(cons_instantiation) {
6   let(foo, call_static(cons, n(5), n(6)));
7   let(five, call_static(foo, cons::hd));
8   let(six, call_static(foo, cons::tl));
9
10  assert_types_equal(five, n(5));
11  assert_types_equal(six, n(6));
12  assert_types_equal(foo, call_static(cons, n(5), n(6)));
13 };
14
15 runtest(cons_instantiation);

```

Next to define a variadic list constructor. This uses C++0x variadic templates for specialized expansion. It's sort of possible without variadic templates, though the result is less elegant. Note that because GCC doesn't yet implement variadic template argument unpacking this is not legal. Hopefully they will implement that soon, but until then it's probably going to be longhand cons invocation.

## 4.2 Identity function

This is primarily useful for a fall-through case in a conditional.

**Listing 33** core/id.hh

```

1 #ifndef CORE_ID_HH

```

```

2 #define CORE_ID_HH
3 #include "module/begin.hh"
4
5 def(id) fn(class x, x);
6
7 #include "module/end.hh"
8 #endif

```

**Listing 34** tests/core/id.cc

```

1 #include "core/cons.hh"
2 #include "core/id.hh"
3 #include "unit/test.hh"
4 #include "unit/fixtures.hh"
5
6 deftest(id_invocation) {
7     assert_types_equal(n(5), call_static(id, n(5)));
8     assert_types_equal(cons, call_static(id, cons));
9 };

```

### 4.3 map, filter, and fold

These can all be implemented in terms of cons-cell juxtaposition, and that's what I'm doing here. (The Church encoding is very convenient for this reason.) Here are the mathematical definitions of these functions:

$$\begin{aligned}
 \text{map } f \text{ } xs &= xs \ \lambda xy. [\text{cons } (f \ x), y] \\
 \text{filter } f \text{ } xs &= xs \ \lambda xy. [(\text{cons } x, y) \ (f \ x \text{ cons } \text{tl})] \\
 \text{fold } f \text{ } (\text{cons } x, xs) &= f \ x \ (\text{fold } f \text{ } xs) \\
 \text{fold } f \text{ } (\text{cons } x, \text{nil}) &= x
 \end{aligned}$$

## 5 $\beta$ -Rewrite Representation

This section outlines the conversion process from a simple  $\beta$ -rewrite calculus to template metaprogramming constructs. This rewrite system then is combined with an eval function to form the basis for the metacircular interpreter defined in [section ??](#).

## 6 Unit and Integration Tests

This section defines a basic unit and integration test library with assertions to test equality of expressions in type-space.<sup>13</sup> It defines some macros that make it very easy to write tests, and enables the preprocessor macros defined in [section 3](#).

### 6.1 Type equivalence

A good approximation for type equivalence is whether a container expanded with one type is assignable to that container expanded with another type (and vice versa, to cover any co/contravariance). This should capture the extensionality of type equivalence without admitting any possibilities that are substantially different.

Listing 35 unit/type-equivalence.hh

```
1 #ifndef UNIT_TYPE_EQUIVALENCE_HH
2 #define UNIT_TYPE_EQUIVALENCE_HH
3
4 namespace lisp {
5 namespace unit {
6
7 template <class c1, class c2>
8 class type_equality_assertion_failed_ {
9     c1 the_left_hand_side_;
10    c2 the_right_hand_side_;
11
12 public:
13     type_equality_assertion_failed_ () {
14         when_testing_assignability (the_right_hand_side_);
15         when_testing_assignability (the_left_hand_side_, false);
16     }
17
18     void when_testing_assignability (c1 c) {
19         the_left_hand_side_ = c;
20     }
21
22     void when_testing_assignability (c2 c, bool b) {
23         the_right_hand_side_ = c;
24     }
25 };
26
27 }
```

---

<sup>13</sup>Since value-dependent types are pure with respect to values, and values are pure with respect to types, this is sufficient to test static values contained within those types as well.

```

28 }
29
30 // The definition of symbol_concat is basically the same as BOOST_JOIN.
31 #define symbol_concat(x, y) symbol_concat_aux(x, y)
32 #define symbol_concat_aux(x, y) x ## y
33
34 #define assert_types_equal(types...) \
35     assert_types_equal_with_name( \
36         symbol_concat(type_equality_check_, __LINE__), types)
37
38 #define assert_types_equal_with_name(name, types...) \
39     typedef ::lisp::unit::type_equality_assertion_failed_<types> name; \
40     name symbol_concat(type_equality_check_var_, __LINE__);
41
42 #endif

```

## 6.2 deftest

This is a quick way to create a scope for running unit tests. The semantic is just like `def()` from [section 3.3](#), but preserves the idea that we're defining a test and may change at some point in the future.

Listing 36 unit/deftest.hh

```

1 #ifndef UNIT_DEFTTEST_HH
2 #define UNIT_DEFTTEST_HH
3
4 #define deftest(name) struct name
5 #define runtest(name) static name symbol_concat(test_enablement_, __LINE__)
6
7 #endif

```

## 6.3 Fixtures

These are some quick ways to construct terminal types.

Listing 37 unit/fixtures.hh

```

1 #ifndef UNIT_FIXTURES_HH
2 #define UNIT_FIXTURES_HH
3
4 namespace lisp {
5 namespace unit {
6
7     template<int n>
8     struct int_wrapper {
9         enum { value = n };

```

```

10 };
11
12 }
13 }
14
15 #define n(x) ::lisp::unit::int_wrapper<x>
16
17 #endif

```

## 6.4 Test definitions

Unit tests should have minimal boilerplate, ideally just one `#include`. This header takes care of importing all of the stuff that would otherwise be test boilerplate.

**Listing 38** unit/test.hh

```

1 #ifndef UNIT_TEST_HH
2 #define UNIT_TEST_HH
3
4 #include "preprocessor/begin.hh"
5
6 #include "unit/type-equivalence.hh"
7 #include "unit/deftest.hh"
8
9 int main () {
10     return 0;
11 }
12
13 namespace lisp {
14     namespace unit {
15         namespace defined_tests {
16         }
17     }
18 }
19
20 using namespace lisp;
21 using namespace lisp::unit;
22
23 #endif

```

## 7 Resources

This section contains extra files that are helpful for running the examples. Note that this library requires your version of gcc to support a fairly recent C++0x

draft, as specified by `-std=gnu++0x`.

## 7.1 Makefile for introduction examples

This makefile will build all of the examples in [section 1](#). It is available in the source distribution as `src/examples/introduction/makefile`, and should be run from inside `src/examples/introduction`. Alternatively, all of the examples can be compiled by using the makefile in `src/examples`.

**Listing 39** `examples/introduction/makefile`

```
1 WORKING = first-order-functions higher-order-functions indirect-functions \  
2          apply-two-function specialization inner-specialization fibonacci \  
3          fibonacci-piecewise linked-list church-lists  
4  
5 BROKEN  = indirect-functions-broken inner-specialization-broken \  
6          fibonacci-piecewise-broken self-reference-broken  
7  
8 BASE_DIR = ../../  
9 CC       = g++  
10 CC_OPTS = -g -Wall -std=gnu++0x -I$(BASE_DIR)  
11  
12 all: $(WORKING)  
13 broken: $(BROKEN)  
14  
15 .PHONY: clean  
16 clean:  
17     rm -f $(WORKING) $(BROKEN)  
18  
19 %: %.cc  
20     $(CC) $(CC_OPTS) $< -o $@ || true
```

## 7.2 Makefile for tests

This makefile builds the unit and integration tests for the Lisp implementation. The tests should fail at compile-time if an assertion is not satisfied. This file should be run from `src/tests`.

**Listing 40** `tests/makefile`

```
1 UNIT      = core/cons core/id  
2 INTEGRATION =  
3  
4 BASE_DIR  = ../../  
5 CC       = g++  
6 CC_OPTS  = -g -Wall -std=gnu++0x -I$(BASE_DIR)  
7
```

```
8 all: $(UNIT) $(INTEGRATION)
9
10 .PHONY: clean
11 clean:
12     rm -f $(UNIT) $(INTEGRATION)
13
14 %: %.cc
15     $(CC) $(CC_OPTS) $< -o $@ || true
```
